ABSTRACT

Phthalocyanine-based light harvesting nanomaterials are attractive due to their low cost, eco-friendly properties and sensitivity in the red region of the solar spectrum. However, for any practical application, phthalocyanines need to be chemically modified for anchoring groups with wide-band semiconducting nanomaterials. In this paper, zinc phthalocyanine (ZnPc) was functionalized with two carboxyl groups containing a biologically important ligand, tartrate, using a facile wet chemistry route and duly sensitized zinc oxide (ZnO) to form nanohybrids for application in photocatalytic devices. The nanohybrids have been characterized using a high-resolution transmission/scanning electron microscope (HRTEM, FEG-SEM), X-ray diffraction (XRD), steady-state infrared/UV–vis absorption and emission spectroscopy for their structural details and optical properties, whereas the ultrafast dynamical events, which are key for understanding the photocatalytic activities, were monitored using picosecond resolution fluorescence techniques. More specifically, vibrational spectroscopy (FTIR) revealed the covalent connection of ZnPc with the host ZnO nanoparticles via the tartrate ligand. The efficiency of the material for photocatalysis under red light irradiation was found to be significantly enhanced compared to bare ZnO. A mechanistic pathway for the formation of photo-induced reactive oxygen species (ROS) in an aqueous medium for the photocatalytic efficacy was investigated. To make a prototype for a potential application in a flow device for water decontamination, we have sensitized ZnO nanorods (ZnO NR) with tartrate-functionalized ZnPc. The molecular proximity of ZnPc to the ZnO surface has been confirmed by picosecond resolution Förster Resonance Energy Transfer (FRET) from the intrinsic emission of surface defects of ZnO NR to the attached ZnPc. The excited-state electron transfer dynamics, as revealed by a picosecond resolution fluorescence study (TCSPC), is in good agreement with the enhanced charge separation at the interface of the nanohybrid. The enhanced photoresponse, wavelength-dependent photocurrent of the sensitized nanorods and photodegradation of a model water pollutant in a prototype device format confirmed the potential use of the nanohybrids in water purification.

1. Introduction

The choice of photo-sensitizers in solar light-harvesting applications, including dye sensitized solar cells (DSSC) and visible light photocatalysis (VLP) is very important. In most cases, polypyridyl ruthenium complexes are likely choices for such applications [1–4]. While the complexes work reasonably well in visible light, the main drawback of such complexes is a lack of reasonable absorption in the near-IR region. Given that IR energy accounts for 49% of the solar spectrum, an extended red response of the sensitizers is necessary to improve the device efficiency [5]. Phthalocyanines (PCs) have been used in light-harvesting applications, including in polymer-based hybrid DSSC [6], to complement the optical absorption of the polymer in the red region of the solar spectrum. The chemical structures of the PCs are characterized by an aromatic monocylic ligand carrying clouds of delocalized π-conjugated electrons and a central metallic atom with typically 2+ oxidation states playing the role of electron donor to the ligands. Zinc phthalocyanines (ZnPc) are a class of PCs whose main electronic features are explained in detail using DFT [7] and are represented schematically in Fig. 1. ZnPc is usually modified by the addition of anchoring groups for light-harvesting applications [8–13].
In this manuscript, a facile means to attach a biologically important ligand, tartrate, to the central metal of ZnPc using simple wet chemistry was employed. We have made nanohybrids of tartrate-functionalized ZnPc with zinc oxide (ZnO) of different morphologies (particles and nanorods) for light-harvesting applications or red light photocatalysis. Although titania (TiO$_2$) was reported to be a more efficient charge separator from the excited sensitizer in light harvesting, recently DSSC based on ZnO have attained efficiency that is comparable to titania [6]. Moreover, ZnO has emerged more recently in the framework of light-harvesting devices as an alternative to titania because of its flexibility in materials synthesis and significant electron mobility [14].

Fourier transform infrared (FTIR) spectroscopy reveals attachment of the tartrate ligand through a carboxylate end to the ZnO NP, X-ray diffraction (XRD) confirms the intactness of the crystal structure of ZnO upon functionalization with tartrate. We have also studied the photocatalytic activity of the nanohybrid under red light illumination with a model water pollutant, methyl orange (MO), and found significant enhancement, which is found to be a manifestation of enhanced ROS formation from the nanohybrid in aqueous solution. To use the functional material (nanohybrid) in a flow device for the decontamination of polluted water, we have used ZnO nanorods (ZnO NR) on a glass plate duly functionalized with tartrate–ZnPc. The intrinsic emission of the ZnO NR and its spectral overlap with the absorption spectrum of ZnPc reveals Förster Resonance Energy Transfer (FRET) from the surface of the NR to the attached ZnPc, confirming the close proximity between the sensitizer ZnPc to the host ZnO NR. We have confirmed enhanced photocurrent under visible light and measured the wavelength-dependent photocurrent in the sensitized ZnO NR. A prototype of the flow device has also been made and tested for potential application in decontamination of the model water pollutant (MO).

2. Experimental section

2.1. Reagents

Zinc acetate dihydrate, ZnO (~30 nm), methyl orange, zinc phthalocyanine (ZnPc), tartaric acid, zinc nitrate hexahydrate, and hexamethylenetetramine were purchased from Sigma-Aldrich. All compounds were of the highest commercially available purity and used as received. Ultrapure water (Millipore System, 18.2 MΩ cm) and ethanol (> 99% for HPLC, purchased from Sigma-Aldrich) were used as solvents. Analytical-grade chemicals were used for synthesis without further purification. Dimethyl sulfoxide (DMSO) and sodium hydroxide (NaOH) were purchased from Merck.

![Fig. 1. (a) High-resolution transmission electron microscopy (HRTEM) of ZnO NP. Inter-fringe distance of 0.245 nm is consistent with (002) planes of the ZnO crystal. (b) UV–vis absorption spectra of ZnPc in DMSO and the nanohybrid are shown. The absorption spectrum of the suspended NPs without sensitization is shown for comparison.](image)

![Scheme 1. (a, b) Molecular structure of the sensitizer zinc phthalocyanine (ZnPc) and the ligand tartrate are shown. (c) The nanohybrid: possible molecular attachment of ZnPc with ZnO crystal through the tartrate ligand is indicated. (d) Schematic of the prototype flow device using the nanohybrid as the functional material is shown.](image)
2.2. Sensitization of ZnPc on the ZnO NP surface through tartrate ligands

Tartrate has been chosen over other potential organic molecules, including citrate and L-serine, as a ligand for the following reason. The yield of the ligand-functionalized ZnPc is found to be highest in the case of tartrate, as is evident from the following experiment. The three ligands in the aqueous phase and ZnPc in chloroform were stirred for 12 h. Then, the aqueous phase was separated and emission of the ZnPc was monitored upon excitation at 633 nm. The concentration of the complex in the aqueous phase was maximum for the tartrate-containing solution, indicating the strongest binding between tartrate and ZnPc among the three ligands. A 0.5 mM ZnPc (C32H16N8Zn) solution was prepared in dimethyl sulfoxide (DMSO) with constant stirring for 1 h. Then, the tartrate-functionalized ZnO NPs were added to the 0.5 mM ZnPc solution in a dimethyl sulfoxide (DMSO)–deionized (DI) water (1:1, v–v) mixture and stirred for 12 h under dark conditions. After the sensitization process, the solution was centrifuged for a few minutes and the supernatant clear solution of unattached dyes was removed. Then, the sensitized material was washed with a DMSO–water mixture several times to remove any unattached dye. The nanohybrid was then dried in a water bath and stored in the dark until further use.

2.3. Synthesis of ZnO NRs

Zinc acetate dihydrate, Zn(CH3COO)2 2H2O (Merck), zinc nitrate hexahydrate, Zn(NO3)2 6H2O (Sigma-Aldrich), hexamethylenetetramine, C6H12N4 (Aldrich) were used as the starting materials for a low temperature hydrothermal synthesis of ZnO NRs on FTO substrates. Detailed processes for the hydrothermal growth of single-crystal ZnO NRs are described in our previous reports[15–17]. In brief, a ZnO seed layer was initially deposited on cleaned glass substrates by the spray-pyrolysis method at 100 °C using 10 mM zinc acetate solution in isopropanol. The seeded glass substrates were then annealed in air at 350 °C for 5 h and used for the hydrothermal growth of the ZnO NRs. An aqueous solution of zinc nitrate (20 mM) and hexamethylenetetramine (20 mM) was used as the precursor solution for the ZnO NR growth, which was carried out at 90 °C for 40 h. This led to the growth of ZnO NRs with a length of approximately 2–3 μm and diameter of 80–100 nm. To maintain a constant growth rate of the ZnO NRs during the hydrothermal process, the old precursor solution was replaced with a fresh solution every 1 h. The as-obtained ZnO NR samples were then taken out of the reaction vessel and rinsed thoroughly with DI water to remove unreacted residues. Finally, the samples were annealed in air at 350 °C for 1 h prior to the study.

2.4. Sensitization of ZnPc on the ZnO NR surface through tartrate ligands

The functionalization of ZnO NRs with tartrate ligands was carried out at room temperature in the dark by immersing the glass plates with ZnO NRs into a 0.5 mM tartrate aqueous solution (pH adjusted to 9 by NaOH) for 12 h. After that, the plates were washed with distilled water several times. For ZnPc sensitization, a 0.5 mM ZnPc solution, C32H16N8Zn, was prepared in dimethyl sulfoxide (DMSO)–water mixture several times to remove any unattached dye. The nanohybrid was then dried in a water bath and stored in the dark until further use.

2.5. Characterization methods

Field Emission Scanning Electron Microscopy (FESEM, QUANTA FEG 250) was used to investigate the surface morphology of the

Fig. 2. (a) Cyclic voltammograms of ZnPc (red) and ZnPc attached to tartrate ligands (ZnPc–Tar, dark cyan). The CVs were measured in DMSO-aqueous KOH solution at 0.1 V s⁻¹ scan rate and Ag/AgCl as reference electrode. (b) FTIR of the nanohybrid, ZnO NPs and tartrate are shown. A bidentate binding of the tartrate to the ZnO through the carboxylate end is evident (see text). (c) X-ray diffractograms of the nanohybrid and reference ZnO NPs are shown. Intactness of crystal structure of ZnO in the nanohybrid is evident (see text). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)
Transmission electron microscopy (TEM) was carried out using an FEI (Technai S-Twin) instrument with an acceleration voltage of 200 kV. A drop of sample was placed on a carbon-coated copper grid and particle sizes were determined from micrographs recorded at a high magnification of 100,000×. Electrochemical experiments were performed using a CH analyzer potentiostat (CHI1110C). For cyclic voltammetry, a three electrode system consisting of a glassy carbon working electrode, a platinum counter electrode and a reference electrode was employed. All the potentials reported in this paper are referenced to the Ag/Ag⁺ couple and performed in DMSO-1 (M) aqueous KOH solution. X-ray diffraction (XRD) was used to characterize the crystal phase using a PANalytical XPERTPRO diffractometer equipped with Cu Kα radiation (at 40 mA and 40 kV) at a scanning rate of 0.02° s⁻¹ in the 2θ range from 20° to 80°. Fourier transform infrared spectra (FTIR) were obtained with a JASCO FTIR-6300 spectrometer by the KBr Pellet method. For optical experiments, the steady-state absorption and emission were recorded with a Shimadzu UV-2600 spectrophotometer and a Jobin Yvon Fluoromax-3 fluorimeter, respectively. Picosecond resolution spectroscopic studies were carried out using a commercial time correlated single photon counting (TCSPC) setup from Edinburgh Instruments (instrument response function, IRF, 80 ps, excitation at 375 nm, 409 nm and 633 nm). The details of the experimental setup and methodology were described in our earlier report [18, 19]. The average lifetime (amplitude-weighted) of a multi-exponential decay is expressed as $\tau_{av} = \sum c_i \tau_i$. Where $c_i$'s are weighted percentages with time constants of $\tau_i$'s. The Förster Resonance Energy Transfer (FRET) has been studied between donor (ZnO) and acceptor (ZnPc) by following traditional methodology [20, 21] by calculating the Förster distance ($R_0$ in Å)

$$R_0 = 0.211 \times \left[ \kappa^2 n^{-4} Q_{D0} J \right]^{1/6}$$

where $\kappa^2$ is a factor describing the relative orientation in space of the transition dipoles of the donor and acceptor and the magnitude is assumed to be 2/3. The refractive index ($n$) of the medium is considered to be 1.496. $Q_{D0}$, the integrated quantum yield of the donor in the absence of acceptor, is measured to be $3.8 \times 10^{-3}$. $J$, the overlap integral, which expresses the degree of spectral overlap between the donor emission and the acceptor absorption, is given by

$$J(\lambda) = \frac{\int_{\lambda}^{\infty} F_D(\lambda) \epsilon_A(\lambda) \lambda^4 d\lambda}{\int_{\lambda}^{\infty} F_D(\lambda) d\lambda}$$

where $F_D(\lambda)$ is the fluorescence intensity of the donor in the wavelength range of $\lambda$ to $\lambda + d\lambda$ and is dimensionless; $\epsilon_A(\lambda)$ is the extinction coefficient (in M⁻¹ cm⁻¹) of the acceptor at $\lambda$. If $\lambda$ is in nm, then $J$ is in units of M⁻¹ cm⁻¹ nm⁴. The donor–acceptor distance ($r_{DA}$) can be easily calculated using the formula,

$$r_{DA} = \frac{R_0^6 (1 - E)}{E}$$

Here, $E$ is the efficiency of energy transfer. The transfer efficiency is measured using the relative fluorescence lifetime of the donor, in absence ($\tau_D$) and presence ($\tau_{DA}$) of the acceptor,

$$E = 1 - \frac{\tau_{DA}}{\tau_D}$$

Fig. 3. (a) Methyl orange (MO) photodegradation in the presence of the nanohybrid and comparison with bare ZnO NP under white light illumination are shown. (b) Decrease in the rate of MO photodegradation in the presence of Cu²⁺ and after N₂ purging compared to that of the nanohybrid alone. (c) Photocatalytic activity of the nanohybrid under red light (optical irradiance spectrum is in the inset) illumination is shown. The reference for bare ZnO NPs does not show any activity under red light. (d) Red light-induced reactive oxygen species (ROS) generation in the presence of nanohybrid and comparison with ZnO and control (DCFH) in aqueous solution are shown.
deposited on FTO substrates were used as counter electrodes. The platinum (Pt) NPs were deposited on the FTO substrates by thermal decomposition of a 5 mM platinum chloride, H2PtCl6•H2O, and Fluka solution in isopropanol at 385 °C for 30 min. Nanohybrids were used as the photoelectrode and the two electrodes were placed on top of each other with a single layer of 50-μm-thick surlyn 1702 (Dupont) as a spacer between the two electrodes. A liquid electrolyte (1 M KCl) was used as the hole conductor and filled in the inter-electrode space by using capillary force, through two small holes (diameter=1 mm) pre-drilled on the counter electrode. Finally, the two holes were sealed using another piece of surlyn to prevent leakage of the electrolyte. In all of our experiments, the active area of light exposure was fixed at 1 cm². The wavelength-dependent photocurrent is measured using a homemade setup with a Bentham monochromator and dual light (tungsten and xenon) sources.

3. Results and discussion

The chemical structure of zinc phthalocyanine (ZnPc), tartrate ligand and a possible binding site for the formation of the nanohybrid are shown in Scheme 1. A typical high-resolution transmission electron microscopic (HR-TEM) image of ZnO NPs is shown in Fig. 1a. The lattice fringe of ZnO NP shows an interplanar distance of ~0.245 nm, corresponding to the spacing between two (002) planes [23]. The average particle size is estimated to be ~28 nm. Fig. 1b shows the UV–vis absorption spectra of ZnPc in DMSO and the nanohybrids. The absorption spectrum of the suspended ZnO NPs is also shown in Fig. 1b as a reference. The intactness of the optical spectrum of ZnPc in the nanohybrid is confirmed from the studies. In order to investigate the attachment of the tartrate ligand to the ZnPc, cyclic voltammetry experiments were performed as shown in Fig. 2a. Two observed redox processes are associated with ring based processes, Zn(II)Pc2+/Zn(II)Pc3− and Zn(II)Pc3+/Zn(II)Pc4− as ZnPc complexes are not known to show redox activity at the central metal [24]. The redox potentials (E1/2) values of ZnPc are 0.62 V and 1.26 V vs Ag/AgCl in DMSO-1 (M) aqueous KOH solution for Zn(II)Pc2+/Zn(II)Pc3−, Zn(II)Pc3+/Zn(II)Pc4− couples, respectively. Whereas the E1/2 values of ZnO NPs attached to tartrate ligand (ZnPc-Tar) are shifted to 0.68 V and 1.30 V, respectively. The shift in the redox potentials can be attributed to the binding of tartrate ligand at the axial position of the ZnPc [25]. The Fourier transform infrared (FTIR) technique is used to investigate the binding mode of the carboxylic group of the tartrate on the ZnO NP surface because the attachment is very crucial for efficient binding of ZnPc and eventually for light-harvesting applications. For free tartrate, stretching frequencies of the carboxylic group are located at 1630 cm⁻¹ and 1412 cm⁻¹ for antisymmetric and symmetric stretching vibrations, respectively, as shown in Fig. 2b. When tartrate is attached to ZnO, the stretching frequencies of the carboxylic group are located at 1630 cm⁻¹ and 1478 cm⁻¹ for antisymmetric and symmetric stretching vibrations, respectively. The shifting of the stretching frequencies clearly indicates the formation of a covalent bond between the ligand tartrate and the host ZnO NPs [22]. The difference between the carboxylic stretching frequencies, \( \Delta = \nu_{as} - \nu_{sym} \) is useful in identifying the bonding mode of the carboxylic ligand [26]. The observed \( \Delta \) value for the hybrid material is 152 cm⁻¹, which is smaller than that of free tartrate (318 cm⁻¹). This observation reveals that the binding mode of tartrate on the ZnO surface is predominantly bidentate. The XRD study (Fig. 2c) on the bare ZnO NPs (2θ range from 20° to 70°) and upon sensitization with tartrate-functionalized ZnPc shows characteristic planes of wurtzite ZnO, (100), (002), (101), (102), (110), (103), (200), (112) and (201). The intactness of the crystal planes of ZnO upon sensitization with tartrate-ZnPc is also clear from the study. It has to be noted that (002) planes are more polar than (100) and (101) planes. Mclaren et al. [27]

2.7. Photocurrent under white light illumination and wavelength-dependent photocurrent measurements

Photocurrent measurements were conducted in the device geometry described earlier [18,22]. For the measurement, platinum NPs were deposited on FTO substrates as working electrodes. The suspension was irradiated with a red LED (50 W) and also with a xenon lamp (300 W) for UV light illumination has been tested for photodecomposition of methyl orange (MO, taken as a model pollutant) in water. The percentage degradation (%DE) of MO was determined using equation 5

\[
\% \text{DE} = \frac{l_0 - l}{l_0} \times 100
\]

where \(l_0\) is the initial absorbance of MO at \(\lambda_{max}=460\) nm and \(l\) is the absorbance of MO after light irradiation.

2.6. Photocatalytic tests

The photocatalytic activity of the nanohybrid under UV–vis light illumination has been tested for photodecomposition of methyl orange (MO, taken as a model pollutant) in water. The absorption spectrum of the suspended ZnO NPs is also shown in Fig. 1b as a reference. The intactness of the optical spectrum of ZnPc in the nanohybrid is confirmed from the studies. From the average lifetime calculation for the nanohybrid, we obtain the effective distance between the donor and the acceptor \((r_{DA})\) using the above equations.
have shown that the terminal polar faces are more active surfaces for photocatalysis than the nonpolar surfaces perpendicular to them.

Fig. 3a shows the results of the investigation of photocatalytic efficiency of the nanohybrid under white light irradiation (λ ≥ 365 nm) in an aqueous environment. The test water under investigation contains methyl orange (MO) and the model water contaminant. From the experimental data, a significant enhancement of the photocatalytic efficiency in the case of nanohybrids compared to that of the bare ZnO is clearly evident. During photocatalytic reaction, photoinduced electrons and holes escape recombination and migrate to the semiconductor surface which consequently generates (in the presence of oxygen and water) highly oxidative radicals, that can degrade the organic pollutants.

In order to investigate the role of reactive oxygen species (ROS), the photocatalysis experiments were performed after N2 purging for 1 h which drives out the dissolved oxygen. The decrease in the photocatalytic activity as shown in Fig. 3b confirms that the mechanism is mainly through ROS [28]. The photocatalysis rate also decreases in the presence of Cu2⁺ which is a well-known scavenger of super oxides and photogenerated electrons [29,30].

The photocatalytic efficiency of the nanohybrid under red light illumination (620 nm) is also monitored, as shown in Fig. 3c. The nanohybrid exhibits enhanced photocatalytic activity under red light as the sensitizer absorbs in the same region, whereas bare ZnO NPs show no activity under red light because of the lack of absorption in the visible or near infrared region. Comparison with the bare sensitizer ZnPc is difficult to make because the sensitizer is completely insoluble in water. The quantum yield (No of contaminant molecules reacted per incident photon) of the methyl orange degradation reaction in the presence of nanohybrid under white and red light irradiation is found to be 7.0/C0 6 and 4.6/C0 6, respectively. The quantum yield values are consistent with the reported literature for methyl orange degradation [31] by dye-sensitized TiO2 nanoparticles under visible light irradiation through ROS pathway. Our observation is consistent with the enhanced photocatalytic activity of other nanohybrids reported in the literature [18,32,33]. One of our earlier studies explored the higher efficiency of the photocatalytic activity of the

![Fig. 5.](image-url) (a) Spectral overlap of the emission of ZnO NR and the absorption spectrum of ZnPc is shown. (b) Emission from ZnO NRs. Deconvolution of the emission into two peaks (P1 and P2) is also shown. Relatively higher quenching of P2 in the nanohybrid compared to bare ZnO NR is evident. (c, d) picosecond resolved emission transients of ZnO NR and nanohybrid detected at 550 nm (P1 position) and 610 nm (P2 position), respectively. Higher quenching efficiency for P2 is consistent with steady-state spectra shown in (b).

protoporphyrin-IX–ZnO nanohybrid under green light irradiation through the formation of enhanced reactive oxygen species (ROS) in the medium [22]. The ROS generation in the present case is also monitored directly by the dichlorofluorescin–dichlorofluorescein (DCFH–DCF) conversion in an aqueous medium. DCFH is a well-known marker for ROS detection [34]. ROS oxidize non-fluorescent DCFH to fluorescent DCF, and the emission intensity of the DCF was monitored with time as shown in Fig. 3d. In the presence of nanohybrids, maximum enhancement in fluorescence intensity was observed under red light irradiation. In a control experiment, ZnO NPs show insignificant ROS generation under red light illumination because the NPs lack photon absorption in the red region of the optical spectrum. It has to be noted that we cannot compare the efficacy of ROS generation of bare ZnPc as the sensitizer itself is insoluble in water. Time-dependent DCF emission in the absence of the ZnO/nanohybrid is also shown as a control experiment.

To explore the application potentiality of the nanohybrids, we have sensitized ZnO nanorods (ZnO NR) with ZnPc through the tartrate ligand and formed a flow device as shown in Scheme 1c. The SEM images of ZnO NRs used in the flow device are shown in Fig. 4a, top view and Fig. 4b, side view. The ZnO NRs are found to be 2–3 μm in length and have diameters of 80–100 nm. The synthesized NR surfaces without sensitization were found to be emitting at 590 nm due to the intrinsic oxygen vacancy in the material [35]. We have exploited FRET from the NR surface to the attached ZnPc due to their significant spectral overlap as shown in Fig. 5a. A significant quenching of the NR emission is shown in Fig. 5b. The broad NR emission is composed of two bands; One arises from the doubly charged vacancy center (V_{6o}^{--}) located at 610 nm (P_2), and the other arises from the singly charged vacancy center (V_{6o}^{-}) located at 550 nm (P_1) [36,37]. The emission intensity of ZnO NRs in the nanohybrid decreases considerably compared to that of free ZnO NRs, which can be attributed to the efficient non-radiative photo-induced processes from ZnO NRs to the ZnPc.

The photoconductivity measurement [22] of the nanohybrid film was carried out to better understand the contribution of photo-induced charge separation to the net photocurrent in the device (Scheme 1c). Fig. 6a shows the photocurrent response for the sensitized ZnO NR thin film under white light illumination. An improved photocurrent was observed for the nanohybrid thin film (~1.8 μA) under illuminated conditions compared to the ZnO NR thin film (~0.6 μA). The contribution of the ZnPc sensitizer to the...
charge separation for better light harvesting in the near red region is evident from Fig. 6b. The wavelength-dependent photocurrents in the device format for the sensitized ZnO NR and the bare ZnO NR are consistent with the absorption spectra of the corresponding materials. In the case of the sensitized ZnO NRs, the additional peak at 650 nm in the photocurrent spectrum compared to that of the bare ZnO NR (peak at 370 nm) is in accordance with that of the 650 nm in the absorption spectrum of the nanohybrid. To investigate a molecular basis for the enhanced photocurrent in the red region of the excitation spectrum, which is close to the absorption of the sensitizer ZnPc, we have performed pico-second-resolved studies. Fig. 7a shows the steady-state emission spectra of the nanohybrid and free ZnPc in a DMSO solution. The concentration of ZnPc was maintained at the same level for both cases. A significant quenching of ZnPc emission upon red light excitation (633 nm) in the former case compared to the latter one is clearly evident from Fig. 7a, revealing excited-state electron transfer from the LUMO of ZnPc to the host ZnO NR in the nanohybrid. Direct evidence of excited-state electron transfer is revealed from picosecond resolution fluorescence transients (excitation 633 nm, Fig. 7b). One additional faster component of 30 ps (93%) in the nanohybrid emission, compared to the single exponential fluorescence decay of ZnPc in DMSO, clearly indicates an ultrafast photo-induced electron transfer in the former case [42,43]. To explore the potential application of the functional materials that have been developed here, we have made a prototype of a flow device as shown in Scheme 1c. The photocatalytic activity of the device under white light illumination works reasonably well for decontamination of the model water pollutant MO. It was confirmed that the generation of enhanced ROS as a result of ultrafast photo-induced charge separation in the sensitized nanohybrid is the reason for the intrinsic catalytic activity of the flow device under red light. This work would find relevance in harvesting in the underutilized red region of the solar spectrum.

4. Conclusion

In summary, we have sensitized ZnO NPs with ZnPc through a tartrate ligand for the light-harvesting application in the red region of the solar spectrum. A variety of spectroscopic and microscopic techniques have been employed to confirm the formation of a nanohybrid of ZnO with the organic ZnPc. We have used the nanohybrid for a potential application of red-light-induced photocatalysis of a model water contaminant, namely MO. In a prototype, we have demonstrated that sensitized ZnO NRs in a flow device under red light illumination work reasonably well for decontamination of the model water pollutant MO. It was confirmed that the generation of enhanced ROS as a result of ultrafast photo-induced charge separation in the sensitized nanohybrid is the reason for the intrinsic catalytic activity of the flow device under red light. This work would find relevance in harvesting in the underutilized red region of the solar spectrum.
